(57) **ABSTRACT**

A composition comprising at least one graphene-supported metal oxide monolith, said monolith comprising a three-dimensional structure of graphene sheets crosslinked by covalent carbon bonds, wherein the graphene sheets are coated by at least one metal oxide such as iron oxide or titanium oxide. Also provided is an electrode comprising the aforementioned graphene-supported metal oxide monolith, wherein the electrode can be substantially free of any carbon-black and substantially free of any binder.

GRAPHENE-SUPPORTED METAL OXIDE MONOLITH

RELATED APPLICATIONS

This application claims priority to U.S. provisional application Ser. No. 61/745,522 filed Dec. 21, 2012, which is hereby incorporated by reference in its entirety for all purposes.

FEDERAL FUNDING STATEMENT

The United States Government has rights in the invention pursuant to Contract No. DE-AC52-07NA27344 between the U.S. Department of Energy and Lawrence Livermore National Security, LLC, for the operation of Lawrence Livermore National Laboratory.

BACKGROUND

Iron is the fourth most abundant element (~5%) in the Earth's crust and the least expensive among all transition metals (which is ~100 times cheaper than minor metals such as cobalt). In its oxide form, iron oxides (e.g., FeO, Fe₂O₃, Fe₃O₄) are green materials with little environmental impact and have been investigated as potential anode materials for high-performance lithium-ion batteries, due largely to their attractive specific capacity. Fe₂O₃ (alpha-Hematite or gamma-Maghemite), for example, carries a theoretical capacity of 1005 mAh/g that is about ~3 times higher than commercial anode graphite (~372 mAh/g), and is among the highest in various transition metal oxides (e.g., TiO₂, V₂O₅, Cr₂O₃, Mn₃O₄, MoO₂, CO₃O₄, NiO, CuO) (see, for example, FIG. 7). The combined traits of low-cost, nontoxic, corrosion-resistant, and facile synthesis have evidently made Fe₂O₃ one of the top candidates as anode materials for lithium-ion batteries. Other metal oxides also are of interest.

Unfortunately, some known hurdles need to be overcome before metal oxides can become the components in lithium-ion batteries, including (1) low electrical conductivity of metal oxides (FIG. 7), which curbs the rate performance; (2) delamination and pulverization of active materials due to the large volume expansion, leading to capacity fading and low cycle life; and (3) scalability, which is desirable for any synthetic approach in order to have practical applications, as the thickness of commercial battery electrodes is typically ~100-200 μm. Various scientific strategies have hitherto been actively pursued and become a voluminous subject of lithium-ion batteries.

Among various approaches, graphene/metal oxides as anode materials have been under intensive investigations, spurred not only by the high specific capacities of metal oxides (see FIG. 7A), but also by the high electrical conductivity, chemical stability, and mechanical robustness of graphene sheets. To date, a number of composite approaches have been developed, including graphene-anchored, -wrapped, -encapsulated, -layered/sandwiched, or -mixed with metal oxide nanoparticles. Sometimes reduced graphene oxides are used.

Despite high gravimetric energy density and discharge/charge rates often witnessed in some of these composites, most approaches adopt simple dispersion or mixture of graphene with metal oxides, leading to certain shortcomings. First, many strategies only work well when the electrode is very thin. The short diffusion pathway of nanoparticles cannot be taken advantage of when the anode becomes thicker (>100-200 μm for commercial applications), as Li⁺

has to diffuse through the thickness of the electrode during charge-discharge. This disadvantage inevitably limits commercialization potential. Second, the majority of electrodes are not carbon-black-free or binder-free. Despite the high electrical conductivity of single sheet graphene, carbonaceous species and/or polymeric binders are required in most of these approaches. These extra fillers increase electrode weight but contribute little to the lithium storage, reducing the overall energy density. In addition, carbon additives could cause pseudocapacitive behavior in the low-voltage cycle range that could undermine the role of graphene. Third, the lack of control in microstructure homogeneity and interface structures, which prevents in-depth understanding of graphene/nanoparticle interaction mechanisms. The addition of conductive carbons or polymer binders further clouds such studies.

Because of above reasons, the performance characteristics of many existing graphene/metal oxides cannot easily scale up with the thickness of the electrode. Novel architecture designs are needed in order to solve these and other challenging issues.

SUMMARY

Embodiments provided herein include compositions, devices, and articles, as well as methods of making and methods of using the compositions, devices, and articles.

One embodiment provides, for example, a composition comprising at least one graphene-supported metal oxide monolith, said monolith comprising (i) a three-dimensional network of graphene sheets crosslinked by covalent carbon bonds, and (ii) at least one metal oxide embedded inside said three-dimensional network.

Another embodiment provides a method comprising: providing a graphene aerogel monolith; immersing said graphene aerogel monolith in a solution comprising at least one metal salt to form a mixture; curing said mixture to obtain a gel; optionally, heating said gel to obtain a graphene-supported metal oxide monolith. In one embodiment, the heating step is not optional but carried out.

Another embodiment provides a method, comprising: providing a porous graphene aerogel monolith; and depositing at least one metal oxide within the porous graphene aerogel monolith by atomic layer deposition to obtain a graphene-supported metal oxide monolith.

Another embodiment provides a device comprising at least one graphene-supported metal oxide monolith, said monolith comprising a three-dimensional structure of graphene sheets crosslinked by covalent carbon bonds, wherein the graphene sheets are coated by at least one metal oxide.

At least one advantage for at least one embodiment is described in the following embodiments including, for example, specific capacities which are thickness independent, high surface area, high electrical conductivity, and mechanical robustness, and combinations thereof.

BRIEF SUMMARY OF THE FIGURES

FIG. 1 shows a schematic illustration of the synthetic procedures for 3D graphene macroassembly (GMA)/Fe₂O₃ hybrids. Step 1, three-dimensional GMA was fabricated by the reduction of graphene oxides using NH₄OH and supercritically dried and annealed at 1050° C. Step 2, the FeOOH nanoparticles were anchored inside 3D GMA by a sol-gel method, followed by additional supercritically-drying and annealing at 515° C. The lower left drawing shows the graphene-tented Fe₂O₃ structure formed by this approach.

FIG. 2 shows microstructures of the as-synthesized graphene macroassembly (GMA) and graphene/Fe₂O₃ hybrids. (A) A TEM image of GMA. (B) and (C), SEM and TEM images of graphene/Fe₂O₃ hybrids, respectively. (D) Particle size distribution histogram of Fe₂O₃, as measured from a total count of 169 nanoparticles using a series of TEM images similar to the one shown in (C). (E) The selected area diffraction pattern of the graphene/Fe₂O₃. The camera length is 520 mm. (F) A high-resolution TEM image of graphene/Fe₂O₃, with Fe₂O₃ nanoparticles highlighted inside squares.

FIG. 3 shows specific capacity, rate performance, and cycle stability of graphene/Fe₂O₃ hybrids. The observed specific capacities of (A) graphene/Fe₂O₃, and (B) pure GMA at various discharge/charge current densities.

FIG. 4 shows selected discharge/charge cycles for (A) pure GMA and (C) graphene/Fe₂O₃, and their corresponding differential capacity curves, (B) and (D), respectively.

FIG. 5 shows surface morphologies of GMA and graphene/Fe₂O₃ after 30 cycles of electrochemical testing. (A) and (B), cross-section SEM images of GMA, and (C) and (D), of graphene/Fe₂O₃. Samples in (A) and (C) were charged to 3V, whereas those in (B) and (D) were fully discharged.

FIG. 6 shows microstructures of graphene/Fe₂O₃ after 30 cycles and in the lithiation state. (A) A low-magnification TEM image of graphene/Fe₂O₃. Some selected particles with back-and-white contrast are highlighted inside circles. (B) A zoomed-in TEM image of graphene/Fe₂O₃ after lithiation. The areas representing Li₂O and Fe nanoparticles are pointed with different white arrows. The size of Fe metal particle is observed smaller than 5 nm, surrounded by semi-amorphous Li₂O phase. (C) A high-resolution TEM image of isolated Fe particles. The inset fast-Fourier transformation (FFT) pattern is obtained from two square areas, which exhibit the same FFT pattern.

FIG. 7. (A) A summary of theoretical specific capacities (C), electrical conductivities (σ), and densities (ρ) of different transition metal oxides as anode candidates for lithium-ion batteries. The order of metal oxides is sorted according to their specific capacities, from high to low. (B) A summary of information and electrochemical performances of graphene/Fe₂O₃, as described herein, as anodes for lithium-ion batteries.

FIG. 8 shows x-ray diffraction data for titanium oxide graphene material. Anatase phase with grain size of ~3 nm was obtained after annealing at 600° C. for 1 hour under N₂ flow.

FIG. 9 shows Raman spectra for titanium oxide graphene material. Raman peaks for titania became stronger after annealing at 600° C. for 1 hour under N₂ flow.

FIG. 10 shows electrochemical measurements for titanium oxide graphene material.

FIG. 11 shows more electrochemical measurements for titanium oxide graphene material (annealed at 600° C. for 1 hour under N₂ flow).

FIG. 12. (A) Nitrogen adsorption/desorption isotherms and (B) pore size distribution for graphene/Fe₂O₃ hybrids.

FIG. 13. Raman spectra of the 3D graphene and a graphene/Fe₂O₃ hybrid sample (containing both α - and γ -Fe₂O₃).

FIG. 14. XRD patterns of two representative graphene/Fe₂O₃ samples. One contains α - and γ -Fe₂O₃ phases, and the other has 100% γ -Fe₂O₃.

FIG. 15. Differential capacity plots of graphene/(α + γ)-Fe₂O₃ (56 wt. % Fe₂O₃). The convoluted nature of the inset oxidation peaks can be seen.

FIG. 16. Additional TEM image of graphene/(α + γ)-Fe₂O₃ (40 wt. %), indicating the faceted nature of as-grown particles as manifested by the rather straight edges in 2D projection.

FIG. 17. A comparison of simulated Li₂O (cubic) diffraction patterns along $\langle 100 \rangle$ zone axis with the FFT pattern (inset) from our experiments. A good match is found. The simulation was performed using the online version of WebEMAPS software.

FIG. 18. A bright-field TEM image of the lithiated graphene/(α + γ)-Fe₂O₃ (40 wt. %) after 30 cycles, showing a partially lithiated particle.

FIG. 19. Microstructures of graphene/(α + γ)-Fe₂O₃ (40 wt. %) after 30 cycles. The final state of the sample is charged to 3V (i.e., delithiated). (A) A TEM image of graphene/Fe₂O₃, showing the faceted characteristics of particles. (B) A high-resolution TEM of a selected particle. (C) The particle size distribution from the count of 101 particles. The fitting by lognormal distribution yields an average particle size of 12.7+/-7.0 nm.

FIG. 20. Selected area diffraction (SAD) pattern taken from a graphene/(α + γ)-Fe₂O₃ (40 wt. %) sample after 30 cycles and charged to the delithiated state (3.0V). The as-synthesized sample contains both α - and γ -Fe₂O₃.

FIG. 21. Bright-field TEM images of graphene/ γ -Fe₂O₃ (56 wt. %) in (A) the as-synthesized state, and (B) the lithiated state after 5 cycles. The particle sizes reported in FIG. 7B are measured from a series of TEM images similar to the ones shown above. The average particle sizes for the as-synthesized γ -Fe₂O₃ and the lithiated state are 8.1+/-1.2 nm (from 100 counts) and 20.6+/-7.5 nm (from 134 counts), respectively.

FIG. 22. The calculated ratio change (h'/a') after the lithiation, as a function of the initial particle shape defined by h/a (see Spherical-cap model section for the details). The blue dashed line denotes (h'/a')/(h/a)=1 (i.e., uniform expansion line). Note the substantial reduction of h'/a' after the lithiation, suggestive of "pancake" shape-change behavior. The calculation parameters are $2a=8.1$ nm, and $2a'=20.6$ nm, both of which are measured by TEM (see FIG. 7B, γ -Fe₂O₃ and FIG. 21). The volume expansion is assumed as ~96%.

FIG. 23 shows specific capacity, rate performance, and cycle stability of graphene/Fe₂O₃ hybrids. The observed specific capacities of (A) graphene/Fe₂O₃, and (B) pure GMA at various discharge/charge current densities.

FIG. 24 shows selected discharge/charge cycles for (A) pure GMA and (C) graphene/Fe₂O₃, and their corresponding differential capacity curves, (B) and (D), respectively.

FIG. 25. (a) Schematics of solid-electrolyte-interphase (SEI) formation on graphene surface upon discharge and its effect on suppressing surface reactions that contribute to reversible Li storage capacity. (b) Schematics of a proposed, possible mechanism for additional reversible capacity that is enabled by Fe₂O₃ particle expansion/shrinkage on top of the graphene surface.

Graphene-Supported Metal Oxide Monolith

A graphene-supported metal oxide can be a monolith that is mechanically robust, electrically conductive, and of high-surface area. Monolith is a term known in the art. Monolith and methods for making monolith are disclosed in, for example, U.S. Pat. No. 5,207,814, U.S. Pat. No. 5,885,953, U.S. Pat. No. 5,879,744, U.S. Pat. No. 7,378,188, U.S. Pat. No. 7,410,718, and U.S. Pat. No. 7,811,711.

The graphene-supported metal oxide monolith can comprise, for example, (i) a three-dimensional network of graphene sheets crosslinked by chemical linkage such as covalent carbon-carbon bond, and (ii) at least one metal oxide embedded in said three-dimensional network. The metal oxide can be in particle form or non-particle form.

The graphene-supported metal oxide monolith can have a thickness of, for example, 100 μm or more, or 200 μm or more, or 250 μm or more, or about 100-1000 μm , or about 200-500 μm .

The graphene-supported metal oxide monolith can be, for example, mesoporous. The average pore size can be, for example, less than 100 nm, or less than 50 nm.

The metal oxide can include, for example, one or more of Fe₂O₃, TiO₂, MnO₂, Mn₃O₄, Fe₃O₄, Co₃O₄, MoO₂, NiO, CoO, CuO, and V₂O₅. Metal oxides can also be used with Mn, Fe, Co, Ni, Cu, Zn, Zr. Also used can be SnO₂, CO₃O₄, V₂O₅, NiCo₂O₄, NiO₂, Al₂O₃ and SiO₂. Combinations of metal oxides can be used.

In some embodiments, the metal oxide is selected from Fe₂O₃, TiO₂, SnO₂, NiO_x, NiCo₂O_x, CoO_x, MnO_x, Al₂O₃, SiO₂, and V₂O₅.

The metal oxide particle can be, for example, a nanoparticle. The average diameter of the metal oxide particle can be, for example, 1-100 nm, or 2-50 nm, or 5-20 nm. In one particular embodiment, the metal oxide particle is a Fe₂O₃ nanoparticle. In another particular embodiment, the metal oxide particle is a TiO₂ nanoparticle.

The weight percentage of metal oxide in the graphene-supported metal oxide can be, for example, 5-95%, or 10-90%, or 20-80%, or 30-60%.

The surface area of the graphene-supported metal oxide can be, for example, of 200 m²/g or more, or 500 m²/g or more, or 700 m²/g or more, or 200-1500 m²/g, or 500-1000 m²/g.

In one embodiment, 50% or more, or 70% or more, or 90% or more of the crosslinking covalent bonds of the three-dimensional network of graphene sheets are sp² bonds.

In one embodiment, the graphene-supported metal oxide monolith is substantially free of graphene sheets interconnected only by physical crosslinks (e.g. Van der Waals forces). In another embodiment, less than 20%, or less than 10%, or less than 5%, or less than 1% of the graphene sheets are interconnected only by physical crosslinks.

In one embodiment, the graphene-supported metal oxide monolith is substantially free of graphene sheets interconnected only by metal crosslinks (e.g., noble metal such as Pd). In another embodiment, less than 20%, or less than 10%, or less than 5%, or less than 1% of the graphene sheets are interconnected only by metal crosslinks.

In one embodiment, the graphene-supported metal oxide monolith is substantial free of graphene sheets with hydroxyl or epoxide functionalities. In another embodiment, 5% or less, or 3% or less, or 1% or less, or 0.5% or less, or 0.1% or less of the carbon atoms in the graphene-supported metal oxide monolith are connected to a hydroxyl or epoxide functionality.

The graphene sheets can be randomly oriented. The graphene sheets can have lateral dimensions of 100 nm or more, 200 nm or more, or 500 nm or more. The surfaces of the graphene sheets can be substantially free of nanoparticles.

In a preferred embodiment, the three-dimensional network of graphene sheets is not made by stacking non-organic material, such as metals, between graphene sheets. Process for Making Graphene-Supported Metal Oxide Monolith

The graphene-supported metal oxide monolith described herein can be prepared by, for example: (i) providing a graphene aerogel monolith; (ii) immersing said graphene aerogel monolith in a solution comprising at least one metal salt to form a mixture; (iii) curing said mixture to obtain a gel; (iv) optionally, heating said gel to obtain a graphene-supported metal oxide monolith. In one embodiment, the graphene-supported metal oxide monolith was obtained without heating. In one embodiment, the heating step is carried out to obtain the graphene-supported metal oxide monolith.

The fabrication of graphene aerogel monoliths are disclosed in US 2012/0034442 and Worsley et al., *Chem. Commun.*, 2012, 48, 8428-8430, both of which are incorporated herein by reference in its entirety.

The solution for immersing the graphene aerogel can comprise, for example, water and/or at least one organic solvent. The organic solvent can include, for example, an alcohol such as methanol, ethanol, propanol, and the like.

The solution for immersing the graphene aerogel can comprise, for example, at least one initiator for the sol-gel reaction. The initiator can be, for example, propylene oxide, trimethylene oxide, dimethylene oxide, and the like.

The metal salt in the solution can comprise, for example, an iron salt, a titanium salt, a manganese salt, a cobalt salt, a molybdenum salt, a nickel salt, a copper salt, and/or a vanadium salt. In one particular embodiment, the metal salt comprises iron nitrate and/or iron chloride. In another particular embodiment, the metal salt comprise titanium alkoxide.

The concentration of the metal salt in the solution can be, for example, 0.02-10 M, or 0.05-5 M, or 0.1-2M. In addition, the molar ratio of the initiator to the metal salt can be tuned to promote nanoparticle nucleation and anchoring on the surface of graphene sheets. The molar ratio of the initiator to

the metal salt can be, for example, 50:1 to 1:1, or 20:1 to 5:1. In a particular embodiment, the metal salt is an iron salt, and the molar ratio of the initiator to the iron salt is about 11:1.

The mixture comprising the graphene aerogel monolith immersed in the solution is subjected to sol-gel reaction. After gelation, the gel is heated to crystallize the metal oxide particle. The gel can be heated at, for example, 200° C. or more, or 250° C. or more, or 300° C. or more, or 350° C. or more, or 400° C. or more, or 450° C. or more, or 500° C. or more, or about 200-800° C., or about 300-600° C. The gel can be heated for, for example, 1-10 hours, or 2-8 hours, or 3-6 hours.

The graphene aerogel monolith can be prepared by, for example: (i) preparing a reaction mixture comprising a graphene precursor suspension and at least one catalyst; (ii) curing the reaction mixture to produce a wet gel; (iii) drying the wet gel to produce a dry gel; and (iv) pyrolyzing the dry gel to produce the graphene aerogel.

Precursors to graphene are known in the art. For example, graphene oxide is a general term for oxidized graphene, which can be a precursor to graphene. Closely related precursors can include, for example, graphite oxide, single layer graphene oxide, exfoliated graphite, and the like.

In one embodiment, the reaction mixture comprises a graphene oxide (GO) suspension. Methods for making GO are known in the art and disclosed in, for example, Hummer, *J. Am. Chem. Soc.*, 80:1339 (1958), which is incorporated herein by reference in its entirety. In one embodiment, the GO suspension is an aqueous suspension. In another embodiment, the GO suspension is a suspension of at least one organic solvents, such as alcohol, dimethylformamide, tetrahydrofuran, ethylene glycol, N-methylpyrrolidone, etc. In one embodiment, the GO suspension is an aqueous suspension made by sonicating GO in deionized water. The time for sonication can range from 0.5-24 hours. The concentration of GO in the reaction mixture can be 0.1 mg/cc or more, or 1 mg/cc or more, or 2 mg/cc or more, or 5 mg/cc or more, or 10 mg/cc or more.

The reaction mixture may also comprise additional reactant known for sol gel reactions, though it is may not be necessary for gelation. In one embodiment, the reaction mixture comprises resorcinol-formaldehyde (RF), phloroglucinol-formaldehyde, phenol-formaldehyde, cresol-formaldehyde, or phenol-furfuryl alcohol. In one embodiment, the reaction mixture is free of RF. In another embodiment, the reaction mixture comprises RF. In a preferred embodiment, the GO-to-RF ratio is 0.1 or more.

The reaction mixture also can comprise at least one sol gel catalyst. In one embodiment, the catalyst is an acid catalyst. In another embodiment, the catalyst is a base catalyst. Catalysts suitable for making graphene aerogels include, but are not limited to, nitric acid, acetic acid, ascorbic acid, hydrochloric acid, sulfuric acid, sodium carbonate, sodium hydroxide, ammonium hydroxide, and calcium sulfate. The reactant-to-catalyst ratio may range from 10 to greater than 1000.

In one embodiment, the reaction mixture is cured at a temperature of 25-100° C. to produce a wet gel. In another embodiment, the reaction mixture is cured for 4-168 hours at a temperature of 85° C. In a further embodiment, the reaction mixture is cured at atmospheric pressure.

In one embodiment, the wet gel is subjected to solvent exchange to remove reaction by-products. Suitable solvent include, but are not limited to, DI water. In another embodiment, the wet gel is subjected to solvent exchange to remove water. Suitable solvents include, but are not limited to, acetone.

In one embodiment, the wet gel is dried in a supercritical gas to produce a dry gel. Suitable supercritical gases include, but are not limited to, supercritical CO₂. In another embodiment, the wet gel is dried under ambient temperature and pressure for an extended time such as at least 24 hours.

In one embodiment, the dry gel is pyrolyzed in an inert gas to produce a graphene aerogel. Suitable inert gases include, but are not limited to, N₂. The drying temperature can be 500° C. or more, or 800° C. or more, or 1000° C. or more.

In one embodiment, a graphene aerogel can be further activated to produce an activated aerogel with increased surface area. In one embodiment, the graphene aerogel is thermally activated in an oxidizing atmosphere. Suitable oxidizing atmospheres include, but are not limited to, CO₂. The temperature for the thermal activation can be 900° C. or more, or 1000° C. or more.

In an alternative embodiment, the graphene-supported metal oxide monolith is prepared by: (i) providing a porous graphene aerogel monolith; and (ii) depositing at least one metal oxide within the porous graphene aerogel monolith by atomic layer deposition to obtain a graphene-supported metal oxide monolith.

Devices Comprising Graphene-Supported Metal Oxide

The graphene-supported metal oxide monolith described herein can be used in a variety of devices. For example, it can be used in electrodes, batteries, capacitors, supercapacitors, sensors, actuators, membranes, catalyst supports, and hydrogen storage devices.

In one particular embodiment, the graphene-supported metal oxide monolith described herein is used in a lithium battery electrode. The electrode can be, for example, substantially free of any carbon-black. The electrode can be, for example, substantially free of any carbon additives. The electrode can be, for example, substantially free of any binders, such as polymer binders. The electrode can be, for example, substantially free of metal current collectors. The electrode can have a thickness of, for example, 100 μm or more, or 200 μm or more, or 250 μm or more, or 100-1000 μm, or 200-500 μm.

In addition to the electrode comprising the graphene-supported metal oxide monolith, the device can further comprise, for example, at least one counter electrode, at least one electrolyte, at least one separator, and/or at least one current collector. The electrolyte can be a lithium salt, and the device can be a lithium ion battery.

Where the metal oxide is Fe₂O₃, the lithium ion battery can have a discharge capacity of, for example, at least 500 mAh/g, or at least 800 mAh/g, or at least 1000 mAh/g at 100 mA/g after 30 cycles. The lithium ion battery can have a reversible capacity of, for example, at least at least 500 mAh/g, or at least 700 mAh/g, or at least 900 mAh/g at 141 mA/g (0.14C). The lithium ion battery can have a reversible capacity of, for example, at least at least 400 mAh/g, or at least 500 mAh/g, or at least 600 mAh/g at 503 mA/g (0.5C).

Where the metal oxide is TiO₂, the lithium ion battery can have a reversible capacity of, for example, at least at least 50 mAh/g, or at least 100 mAh/g, or at least 200 mAh/g at 168 mA/g (1C). Long-term cycle stability testing can show longer life. Fast charging can be also achieved.

Graphene Monolith Comprising Lithiated Metal Oxide

Further embodiments of the monolith described herein comprises (i) at least one graphene-based monolith comprising a three-dimensional network of graphene sheets crosslinked by covalent carbon bonds, wherein said three-dimensional network of graphene sheets defines a surface area, (ii) a first region on said surface area comprising at

least one lithiated metal oxide, wherein the first region is not covered by SEI, and (iii) a second region on said surface area covered by SEI.

The surface area covered by the first region can be, for example, at least 10%, or at least 20%, or at least 30%, or at least 40%. The surface area covered by the second region can be, for example, less than 90%, or less than 80%, or less than 70%, or less than 60%, or less than 50.

In some embodiments, the metal oxide is selected from Fe_2O_3 , TiO_2 , SnO_2 , NiO_x , NiCo_2O_x , CoO_x , MnO_x , Al_2O_3 , SiO_2 , and V_2O_5 .

Additional embodiments are provided in the following non-limiting working examples.

WORKING EXAMPLES

Additional embodiments are also provided in the following non-limiting working examples. For example, graphene-supported metal oxide monoliths were prepared and characterized.

Example 1

Iron Oxide/Graphene Monolith

Material Synthesis

Thick (~250 μm), carbon-black- and binder-free, nanoporous graphene/ Fe_2O_3 hybrids were synthesized through a chemical sol-gel method. In contrast to previous approaches (and in order to achieve thick and binder free electrodes), the synthetic strategy began with a novel 3-dimensional (3D) graphene macroassembly (GMA) scaffold, FIG. 1 (Step 1), using the method reported in Worsley et al., *Chem. Commun.* 2012, 48 (67), 8428-8430. The as-synthesized GMA has a thickness of ~250 μm , a density of ~70 mg/cm^3 , a very high surface area up to ~1500 m^2/g , high electrical conductivity (~2 S/cm), and nanometer-sized open porous distributions, a bulk part of which is smaller than 10 nm. Both the density and surface area of the GMA are higher than most 3D graphene assemblies reported in the literature (see Chen et al., *Nature Mater.* 2011, 10 (6), 424-428). The GMA is also mechanically robust, with a high compressive failure strain of 80-100%, making it suitable for electrode applications.

After GMA synthesis, the 3D GMA was immersed in an ethanolic solution of Fe (III) salt (e.g. iron nitrate, iron chloride) to which an initiator (e.g. propylene oxide, trimethylene oxide) was added (i.e., Step 2 in FIG. 1) (see Gash et al., *Chem. Mater.* 2003, 15 (17), 3268-3275). Iron salt concentrations ranged from 0.175 to 1.4 M. As previously reported (Worsley et al., *Chem. Mater.* 2011, 23 (12), 3054-3061; Worsley et al., *J. Mater. Chem.* 2009, 19 (31), 5503-5506), preferential nucleation of the nanoparticles on high surface area carbon can be achieved when the sol-gel chemistry is appropriately tuned. In this case, the molar ratio of initiator-to-Fe was set to 11:1 in order to promote nanoparticle nucleation and anchoring of FeOOH nanoparticles on the surface of graphene sheets, instead of in solution. After the particles were formed, the coated assembly was fired at 515° C. under nitrogen for 3 hours to convert FeOOH to Fe_2O_3 .

Characterization and Analysis

The microstructures of the as-synthesized pure GMA and graphene/ Fe_2O_3 hybrids are exhibited in FIG. 2. For pure GMA, a transmission electron microscopic (TEM) image shown in FIG. 2A indicates that it is mostly comprised of single-layer graphene sheets; but stacked layers are visible with a measurable interlayer spacing of ~0.385 nm. Raman

spectroscopy characterizations reveals that the as-synthesized 3D GMA has a D/G band ratio of 1.37. After Fe_2O_3 deposition, scanning electron microscopy (SEM) studies (FIG. 2B) confirmed that nanoparticles uniformly embedded among 3D graphene networks. The existence of Fe_2O_3 was further confirmed by Raman spectroscopy, which shows that the as-synthesized 3D GMA has a D/G band ratio of 1.37 (FIG. 12).

At 40% Fe_2O_3 weight load, the Brunauer-Emmett-Teller (BET) measurements using nitrogen isothermal adsorption indicate that the hybrid has a specific surface area of ~680 m^2/g , which is higher than those reported in the literature (Zhou et al., *Chem. Mater.* 2010, 22 (18), 5306-5313). In addition, all pores inside the hybrids are smaller than 100 nm, as determined by Barrett-Joyner-Halenda (BJH) method.

Further, at 56% Fe_2O_3 weight load, the BET measurements using nitrogen isothermal adsorption indicate that the hybrid has a specific surface area of ~700 m^2/g (FIG. 13A). In addition, the bulk part of open pores inside the hybrids is smaller than 10 nm (FIG. 13B), as determined by BJH method. These open nanopores are expected to not only serve as transport channels for electrolyte, but also offer ample room for the volume expansion of metal oxides during the lithiation. As such, these nanoporous structures are one of the key reasons why our electrodes can be ultrathick.

The representative TEM image in FIG. 2C illustrates that the sizes of most Fe_2O_3 nanoparticles are well below 50 nm, as can be better revealed in the statistical particle distribution histogram (FIG. 2D), which indicates an average particle size of ~12.5±5.5 nm. The nanoporous characteristics of GMA are also clearly visible under TEM. The selected area diffraction (SAD) pattern from TEM in FIG. 2E shows a mixture phase of α - and γ - Fe_2O_3 , consistent with the x-ray diffraction results (FIG. 14). The high-resolution TEM investigations, one example of which is shown in FIG. 2F, indicate the good crystalline quality of as-synthesized nanoparticles and tented nature of Fe_2O_3 with most edges of the nanoparticles in tight bond with graphene sheets. These graphene-tented structures not only offer great electron pathway to the nanoparticles during lithiation-delithiation processes, but also allow easy volume expansion and contraction for Fe_2O_3 nanoparticles without having to break electrical contacts.

Electrochemical Performance of Graphene/ Fe_2O_3 -40 wt. % Loading

The electrochemical performance of the graphene/ Fe_2O_3 as anodes was characterized using a half-cell configuration, with Fe_2O_3 weight percentages at 40%. Note that the as-synthesized freestanding films were directly used without any carbon additives, or polymer binders, or metal current collectors. Despite the very large thickness (~250 μm) of the electrodes, graphene/ Fe_2O_3 hybrids showed excellent electrochemical performance, the cycle stability and rate performance of which are illustrated in FIG. 3A. At a current density of 141 mAh/g (i.e., 0.14C, where C=1005 mAh/g), the graphene/ Fe_2O_3 sample exhibited a discharge capacity of ~2020 mAh/g (equivalent to 12.1 Li^+ uptake per Fe_2O_3 molecule based on the total weight) and a charge capacity of ~818 mAh/g at the first cycle. The relatively low charge capacity of the sample in the first cycle is likely due to the poor electrolyte wetting, as the anode did not contain any polymer binders and had ultra-thickness. This is consistent with the lag response of the specific capacity whenever a different discharge/charge rate is applied (see FIG. 3A). As the wetting improved, the charge capacity steadily increased

and stabilized after ~10 cycles at ~922 mAh/g. At a higher current density of 503 mAh/g, the sample had a reversible capacity of ~656 mAh/g, which remains well above the theoretical capacity of graphite and is indicative of good rate performance. Significantly, the reversible capacity of graphene/Fe₂O₃ retained at a value of ~1166 mAh/g (equivalent to 7.0 Li⁺ based on the total weight) at a current density of 100 mAh/g after 30 cycles. These results demonstrated excellent cycle stability of the graphene/Fe₂O₃ hybrids. Since Fe₂O₃ has a theoretical Li⁺ intake of 6 per molecule, the additional reversible capacity (i.e., 1.0 Li⁺ at 100 mAh/g) observed in the hybrids may be related to the formation of reversible organic gel-like films (Larcher et al., *J. Electrochem. Soc.* 2003, 150 (12), A1643-A1650) and/or Li⁺ insertion/intercalation into graphene defect sites or interlayers. Notably, the initial uptake of 12.1 Li⁺ per Fe₂O₃ molecule is higher than all previously reported values, including graphene/Fe₂O₃ and nanosized Fe₂O₃ particles with values of 10.1, 8.8, and 8.6 Li⁺ uptake reported previously (Larcher et al., *J. Electrochem. Soc.* 2003, 150 (12), A1643-A1650; Morales et al., *J. Electrochem. Soc.* 2005, 152 (9), A1748-A1754). Such a large Li⁺ uptake may be related to the pseudocapacitive behavior typically associated with large surface area electrodes (Zhu et al., *ACS Nano* 2011, 5 (4), 3333-3338; Larcher et al., *J. Electrochem. Soc.* 2003, 150 (12), A1643-A1650). Despite the very large thickness of electrodes used in the experiments and the lack of carbon additives and binders, the reversible capacity of the graphene/Fe₂O₃ hybrids at low current density (~100 mAh/g) is higher than other graphene-based hybrids, whereas at higher cycle rates (>503 mAh/g) it is only slightly lower than those reported in the literature (Zhu et al., *ACS Nano* 2011, 5 (4), 3333-3338; Zhou et al., *Chem. Mater.* 2010, 22 (18), 5306-5313). These informative experimental results demonstrate the good rate performance, high cycle stability, and high specific capacities of the graphene/Fe₂O₃ hybrids.

By comparison, the pure GMA samples (~250 μm thick, also without polymeric binders or carbon-black) showed unimpressive cycle stability and low capacity, FIG. 3B. At a current density of 100 mAh/g, the first discharge capacity of GMA achieved a high value of 1077 mAh/g; but decreased to 270 mAh/g in the following charge process. The Coulombic efficiency of the first cycle was ~25%. The discharge capacity in the second cycle decreased to 310 mAh/g, which became stabilized at the level of ~148 mAh/g after 10 cycles. The reversible capacity seen in the GMA was substantially lower than the theoretical capacity of graphite (~372 mAh/g). At a higher current density (>503 mAh/g), pure GMA sample exhibited a capacity that is below ~60 mAh/g. The unimpressive reversible capacity and poor rate-performance observed in GMA are in stark contrast to the large and impressive capacity obtained by 3D graphene/Fe₂O₃ electrodes. This underscores a strong synergistic effect between Fe₂O₃ nanoparticles and graphene.

To study the mechanistic processes occurring in pure GMA and the hybrids, FIG. 4 shows the discharge/charge curves of several selected cycles at a current density of 100 mAh/g and their corresponding differential capacity curves for GMA (FIGS. 4A and B) and graphene/Fe₂O₃ hybrids (FIGS. 4C and D), respectively. During the first discharge of the GMA, the voltage profile showed three reduction peaks at 1.07 V, 0.69 V and <0.5 V (FIG. 4B), the origin of which could be related to the Li⁺ insertion into graphene defects/edges and/or the decomposition of electrolyte and/or the formation of SEI. In the following cycles, however, two high-voltage peaks disappeared, suggesting a nonreversible process associated with these peaks. The last plateau asso-

ciated with <0.5V remained after 10 cycles and thus may represent reversible lithium uptake by GMA. Correspondingly, the two oxidation peaks for pure GMA also disappeared with increasing cycles (inset of FIG. 4B).

For the graphene/Fe₂O₃ sample, FIG. 4D, three main reduction-peaks were identified: 1) the weak peaks around ~1.6 V, which has been attributed to the intercalation of Li⁺ into Fe₂O₃; 2) the strong peaks at 0.6 V-1.0 V, likely due to the conversion reaction (i.e., the iron reduction from Fe³⁺ to Fe⁰):

and 3) the peaks below 0.5V, which could be related to the formation of organic gel-like films or Li⁺ insertion into GMA. During the charge process, the hybrid sample displayed four oxidation peaks at 1.2V, 1.5V, 1.8V, and 2.4V. While the middle two peaks (i.e., O₂ and O₃) have been attributed to the step oxidations of iron from Fe⁰ to Fe³⁺ by lithium exaction, the first (O₁) and last (O₄) peaks are likely linked to GMA as their positions are similar to the oxidation peaks of the pure graphene samples. Unlike GMA, however, these two oxidation peaks in the hybrids remained observable even after 10 cycles; i.e., they became reversible due to the presence of Fe₂O₃/Fe nanoparticles—an intriguing phenomenon that might be linked to the catalytic ability of nanosized Fe₂O₃/Fe particles, as the oxidation peaks were also observed to shift downward compared to those of pure GMA, indicative of easier delithiation processes for graphene inside the hybrids. Although the potential catalytic activities of metal nanoparticles in promoting the decomposition of electrolyte and the formation of gel-like films were suggested previously (Zhou et al., *Chem. Mater.* 2010, 22 (18), 5306-5313; Morales et al., *J. Electrochem. Soc.* 2005, 152 (9), A1748-A1754), it has not been reported that such catalytic activities may also help lithium ion interactions with graphene. This hypothesis is based largely on the earlier experimental documentations that gel-like films can only offer pseudocapacitive behavior that is not consistent with the reappearance of the oxidation peaks for graphene in the synthesized graphene/Fe₂O₃ materials.

Electrochemical Performance of Graphene/Fe₂O₃-56 wt. % Loading

The electrochemical performance of several graphene/Fe₂O₃ samples (with Fe₂O₃ load ratio of 456 wt. %) as anodes is investigated using a half-cell configuration. Note that in all the cases, the as-synthesized freestanding films are directly used without any carbon additives, or polymer binders, or metal current collectors. Despite the very large thickness (~250 μm) of our electrodes, graphene/Fe₂O₃ hybrids (56 wt. % Fe₂O₃) show excellent electrochemical performance, with the cycling stability and rate capability illustrated in FIG. 23A. At a current density of 141 mA/g (i.e., 0.14C if normalized against the Fe₂O₃ capacity of 1C=1005 mAh/g), the graphene/Fe₂O₃ sample exhibits a discharge capacity of ~1633 mAh/g (based on the total weight of the electrode) and a charge capacity of ~796 mAh/g at the first cycle. Since Fe₂O₃ has a theoretical Li⁺ intake of 6 per molecule, the large initial uptake of Li⁺ observed in the graphene/Fe₂O₃ may be related to Li⁺ binding to graphene surface sites (including structural defects and impurity such as residual oxygen), Li⁺ intercalation into graphene layers, the formation of organic gellike films (Laruelle et al., *J. Electrochem. Soc.* 2002, 149 (5), A627-A634), and/or other irreversible products such as the solid electrolyte interphase (SEI) (Arora et al., *J. Electrochem. Soc.* 1998, 145 (10), 3647-3667).

Despite the lack of binders and the very large thickness, we note that the reversible capacity of our electrodes stabilizes in less than 5 cycles at 790 mAh/g, demonstrating the excellent wetting ability of our materials. This is in contrast with some dense films reported in the literature (Wang et al., *ACS Nano* 2010, 4 (3), 15871595). At a higher current density of 503 mA/g, the reversible capacity decreases to ~544 mAh/g, which, however, remains well above the theoretical capacity of graphite (~372 mAh/g) and is indicative of good rate performance. Significantly, the reversible capacity of graphene/Fe₂O₃ stabilizes at a value of ~853 mAh/g at a current density of 100 mA/g after 30 cycles. Among several representative samples we have investigated so far (FIG. 7B), importantly, the reversible capacity of our materials at the low current density (~100 mA/g) after 30 cycles either exceeds or is on par with those reported from other graphene/iron oxides (Zhu et al., *ACS Nano* 2011, 5 (4), 3333-3338; Zhou et al., *Chem. Mater.* 2010, 22 (18), 5306-5313), and even stays at comparably high levels at higher current densities (>503 mA/g). These informative experiments demonstrate the good rate performance, excellent cycling stability, and high specific capacities of our materials.

In comparison, the pure GMA samples (~250 μm thick, also without polymer binders or carbon-black) show severe capacity fading and low reversible capacity, FIG. 23B. At a current density of 74.4 mA/g, the first discharge capacity of GMA achieves a high value of 1077 mAh/g; but plunges sharply to 270 mAh/g in the following charge process. The discharge capacity decreases to 310 mAh/g in the second cycle, and stabilizes at ~148 mAh/g after 10 cycles, which is in fact substantially lower than the theoretical capacity of graphite. At a higher current density (>372 mA/g), the GMA sample exhibits a stable capacity below ~60 mAh/g. Such a low reversible capacity and poor rate performance observed in GMA are in stark contrast to the large and impressive capacity obtained in 3D graphene/Fe₂O₃ electrodes. This underscores the strong synergistic interplays between Fe₂O₃ nanoparticles and graphene.

To survey the mechanistic processes occurring in pure GMA and the hybrids, FIG. 24 shows the charge/discharge curves of several selected cycles at a current density of 100 mA/g and their corresponding differential capacity curves for GMA (FIGS. 24A and 24B) and graphene/Fe₂O₃ hybrids (FIGS. 24C and 24D), respectively. During the first discharge of the GMA, the voltage profile in the differential capacity curves shows three reduction peaks at 1.07 V (R1), 0.69 V (R2) and <0.5 V (R3), FIG. 24B. The origin of these peaks is currently not well understood; but might be related to the Li⁺ binding with graphene defects/edges and/or the decomposition of electrolyte and/or the formation of SEI. In the following cycles, however, two high-voltage reduction peaks (i.e., R1 and R2) disappear, suggesting a nonreversible process associated with these peaks. The last plateau associated with <0.5 V (R3) and the corresponding oxidation peak (O1) (inset of FIG. 24B) remain present after 10 cycles and thus may represent reversible lithium uptake by GMA. Correspondingly, the two oxidation peaks at higher voltages (i.e., O2 and O3) for pure GMA also disappear with increasing cycles.

For graphene/Fe₂O₃ electrodes, the samples with higher load of Fe₂O₃ typically exhibit rather convoluted oxidation peaks that can in principle be separated by proper fitting procedures but are visually challenging to resolve (FIG. 15). For the clarity of presentation, FIG. 24D shows the reduction/oxidation behavior of a sample with 40 wt. % Fe₂O₃. Three main reduction peaks can be identified: 1) the weak

peak around ~1.6 V (R1), which has been attributed to the intercalation of Li⁺ into Fe₂O₃ to form rock salt Li_xFe₂O₃ (x~12); 2) a strong peak at 0.6 V (R2), likely due to the second step of the main conversion reaction:

(i.e., iron reduction from the intermediate compound to Fe⁰), as well as possible contribution of the R2 peak (in FIG. 24B) from graphene; and 3) the peaks below 0.5V (R3), which could be related to the formation of organic gel-like films, Li⁺ insertion into GMA, or irreversible SEI formation. During the charging process, the hybrid sample appears to display five oxidation peaks at <0.5 V (O1), 1.2V (O2), 1.5V (O3), 1.8V (O4), and 2.4V (O5). While the middle two peaks (i.e., O3 and O4) have been attributed to the two step oxidations of iron from Fe⁰ to Fe³⁺ by lithium exaction, the other three peaks (O1, O2, O5) are likely linked to the GMA as their positions are close to the oxidation peaks of the pure graphene samples (O1, O2, O3, respectively). Unlike the pure GMA, however, two oxidation peaks (O2 and O5) in the hybrids remain observable even after 10 cycles; i.e., they become more reversible due to the presence of Fe₂O₃/Fe Nanoparticles—an intriguing phenomenon that has not been reported. We speculate that this may be linked to the volume expansion/contraction of nanoparticles that allows for on-and-off exposure of graphene fresh surface, or related to the catalytic ability of nanosized Fe₂O₃/Fe particles. We note that the catalytic behavior of metal nanoparticles in promoting the decomposition of electrolyte and the formation of gel-like films have been suggested by earlier experiments, which archetypically offer pseudocapacitive behavior. It has not been proposed/reported that such catalytic activities may also help redox reactions between lithium ions and graphene (defects or impurities), which could be associated with the recurring oxidation peaks in our samples.

Surface Morphology

The carbon-black- and binder-free nature of the graphene/Fe₂O₃ electrodes allows further investigation on the surface morphology evolution details after multiple charge-discharge cycles (30 cycles in all the cases reported here), without the complicated effects of extra fillers. FIGS. 5A and 5B indicate that the surface of GMA was relatively clean and smooth in both delithiated (i.e., FIG. 5A) and lithiated (i.e., FIG. 5B) states. The graphene sheets looked slightly thicker and some small voids appear blocked in FIG. 5B, whereas bubble-like features were visible on the surface of graphene in the delithiated state. These “bubbles” were relatively stable under the electron beam used for imaging, which may be related to the reduction products of electrolyte (such as alkyl carbonates); however, continuous gel-like films were observed on the graphene surface. In contrast, the gel-like films were visible for the graphene/Fe₂O₃ sample in the discharged state, FIG. 5C, judged from the rather thick ligaments under SEM. In the charged state, FIG. 5D, it is noticed that much space of the electrode was filled by bulged ligaments, with some voids remaining visible. It is noteworthy to mention that both pure GMA and graphene/Fe₂O₃ remained completely intact after 30 cycles, as evidenced by the well-preserved porous structures and ligaments.

To further investigate the atomic scale mechanisms, TEM samples were prepared after multiple cycles inside the glove box and transferred to the TEM holder using an argon (99.999+% purity) sealed vial. In order to expose and better reveal the nanoparticle morphologies, the electrochemically cycles samples were washed in acetonitrile for more than 10 hrs. The microstructures of graphene/Fe₂O₃ in both fully lithiated and delithiated states were investigated (after 30

cycles), respectively. Under the lithiated state, FIG. 6A, almost all particles exhibited oval or spherical shapes, with black-and-white contrast co-existing often within one single nanoparticle. The round geometries of the nanoparticles were in contrast to the faceted nature of particles seen in the as-synthesized state (see FIG. 2C and FIG. 16). A zoomed-in TEM image shown in FIG. 6B revealed the existence of pure Fe nanoparticle surrounded by Li_2O , as evidenced by the lower contrast of Li_2O and the crystalline morphology of Fe metal. Under the high-resolution TEM, lattice fringes were not readily visible for some Li_2O particles, suggesting the semi-amorphous nature of this phase. These postmortem TEM examinations confirmed the forward reaction of equation (I). Occasionally, however, crystalline Li_2O particles were found, two examples of which are shown in FIG. 6C. Both particles were identified to have the zone axis of $\langle 100 \rangle$, as confirmed by the inset fast-Fourier transformation (FFT) pattern (i.e., both areas have the identical FFT patterns) and diffraction pattern simulations (FIG. 17). The existence of these somewhat isolated Li_2O could be related to the method for preparing the TEM samples. Intriguingly, partially lithiated Fe_2O_3 particles were also located inside the hybrid samples (FIG. 18). This behavior seemed to only occur to some rather large Fe_2O_3 particles (>250 nm). This may suggest that the lithiation/delithiation behavior of metal oxides is very sensitive to their sizes and agglomerations—an observation that supports some earlier reports (Poizot et al., *Nature* 2000, 407 (6803), 496-499). These results accentuate the importance of using nanosized metal oxide particles for Li storage, and echo the good cycle performance of the graphene/ Fe_2O_3 sample. It is found that the round shape nanoparticles can be reversed back to the faceted nanocrystals after they are fully delithiated, as further confirmed by TEM investigations (FIG. 19). The statistical particle size distribution after 30 cycles revealed insignificant average size changes (with a slightly larger standard deviation). This could be attributed to the excellent confinement effect of graphene sheets and the prevalent nanoparticles in the graphene/ Fe_2O_3 samples that are more resistant to pulverization compared to microsized counterparts.

Intriguingly, TEM studies further reveal the disappearance of α -phase for Fe_2O_3 after 30 cycles, as indicated by the SAD pattern (FIG. 20), which suggests that only γ - Fe_2O_3 remains. Furthermore, the SAD pattern no longer yields bright diffraction spots except for the continuous rings, indicating the disintegration of any preexisting large particles or the transformation of single-crystalline to polycrystalline Fe_2O_3 particles upon long-term cycles. The preference of α - Fe_2O_3 transformation to more open cubic structure (i.e., γ - Fe_2O_3) during the Li-ion intercalation has been reported previously (Larcher et al., *Electrochem. Soc.* 2003, 150 (12), A1643-A1650; Jain et al., *Chem. Mater.* 2006, 18 (2), 423-434), which was also found not to revert back to the hexagonal α - Fe_2O_3 . These earlier observations agree with our TEM investigations. This structural irreversibility, however, does not seem detrimental to the electrochemical reversibility of our hybrid materials, as we observe similar specific capacity for two comparison samples [see FIG. 7B, ($\alpha+\gamma$)- Fe_2O_3 vs. γ - Fe_2O_3].

Another important observation from TEM studies is that the average diameter of nanoparticles is found to increase by more than a factor of 2.5 in the lithiated state (FIG. 7B, and FIG. 21). This would have projected a volume expansion of over a thousand percentages provided that nanoparticles were in spherical shape and expanded uniformly during the lithiation. We observed this diameter change trend in both sets of samples that have been examined under TEM. To

understand this apparent paradox of the measured particle sizes and the projected volume expansions, we perform empirical analysis using a spherical-cap model that is consistent with classical nucleation and growth theory of particles on a flat surface. Our calculations, interestingly, suggest that nanoparticles are likely to change their aspect ratios and “spread” preferentially along the graphene/nanoparticles interfaces (i.e., anchored interfaces) upon the lithiation, leading to pancakelike shapes that are supported by our TEM observations. FIG. 6D schematically illustrates the nanoparticles expansion process on graphene sheet (also see FIG. 22). This surprising particle shape change is probably because the conversion reaction, which requires the participation of electrons (Eqn. 1), occurs preferentially on the graphene surface. Because electron transport within metal oxides (Fe_2O_3 and Li_2O) is extremely sluggish due to their poor conductivity, the reaction is kinetically favored to take place on the graphene surface, where electrons can easily reach the reaction front through facile transport within the graphene layer. In addition, ion species (e.g. Li^+ and O^{2-}) are likely to have larger mobility along the solid/graphene or liquid/graphene interface than in the solid phases, further promoting graphene surface as the preferred reaction site. Consequently, the reaction product ($\text{Li}_2\text{O}+\text{Fe}$) upon lithiation has a larger growth rate along the graphene sheets, which produces a significant change in the aspect ratio of the nanoparticles. Furthermore, the average Fe_2O_3 particle size in the delithiated state after 30 cycles measured from TEM images shows insignificant change from the as synthesized state, indicating the reversibility of most particle shape changes.

The finding of the significant shape change of Fe_2O_3 nanoparticles upon (de)lithiation prompts us to propose one possible reason for the synergistic effect observed in the graphene/ Fe_2O_3 hybrid electrodes. After multiple charge/discharge cycles, our graphene/ Fe_2O_3 samples exhibit a reversible capacity that is notably larger than the theoretical capacity of Fe_2O_3 itself (i.e., 56 wt. % Fe_2O_3 contributes a maximum of ~ 563 mAh/g capacity), indicating that the hybrid capacity also derives from sources other than Fe_2O_3 . The presence of multiple peaks and a large background on the differential capacity curves (FIGS. 4C and D) suggests that the extra capacity could have several contributions, involving Li^+ binding to graphene and its structural defects, reaction between Li^+ and impurity (e.g., residual oxygen), and/or the formation of organic gel-like films. While the detailed mechanisms of such auxiliary reactions remain to be clarified, it is plausible that they occur predominantly on the graphene surface because of easy access to electrons. However, a remarkable finding of this work is that these possible reactions only contribute significantly to reversible capacity in the presence of Fe_2O_3 nanoparticles. In the pure GMA sample, the discharge capacity is merely ~ 148 mAh/g after 10 cycles at a current density of 100 mA/g and even lower at higher discharge rates.

It is well known that side reactions (e.g. electrolyte decomposition) cause SEI formation on the surface of battery anodes (e.g. graphite, silicon) during the first few cycles (Arora et al., *J. Electrochem. Soc.* 1998, 145 (10), 3647-3667; Peled, E., *Lithium stability and film formation in organic and inorganic electrolytes for lithium battery systems*, Academic Press: New York, 1983; page 43; Huang et al., *Science* 2010, 330 (6010), 1515-1520). The large irreversible capacity (~ 700 mAh/g) seen in the pure GMA sample upon first discharge may be attributed to the formation of a stable SEI film on graphene surface. This SEI layer could be responsible for the very low reversible capacity in

subsequent cycles by passivating the graphene surface and inhibiting the reversible reactions mentioned above, FIG. 25A. In the graphene/Fe₂O₃ hybrid electrodes, however, we propose that the preferential expansion of nanoparticles on graphene sheets upon lithiation plays a critical role in covering the graphene surface to prevent SEI formation on the top while still allowing the reversible auxiliary reactions to occur forwardly, as illustrated in FIG. 25B. As the particles shrink during delithiation, the surface underneath is re-exposed to the electrolyte and becomes delithiated. The graphene surface around Fe₂O₃ nanoparticles can thus remain SEI-free upon cycling and contribute to the reversible capacity. This scenario is consistent with the persistent appearance of the graphene-related oxidation peaks (O2 and O5) on the differential capacity curves (FIG. 24D).

To estimate the surface area “protected” by the nanoparticles, we measured the average particle size of a hybrid sample (56 wt. % Fe₂O₃) consisting of only γ -Fe₂O₃ from TEM images, which is 8.1 nm in the pristine state and 20.6 nm in the lithiated state. Using these data and assuming that the pristine Fe₂O₃ particles have a hemispherical shape, a simple calculation shows that the nanoparticles will cover ~41% of the total graphene surface area in the lithiated state (up from 6% in the delithiated state). The actual coverage may be even higher considering that we use the upper limit of GMA’s measured specific surface area (~1500 m²/g) in the calculation and the graphene sheets in our sample are highly curved and could make contact with Fe₂O₃ particles on multiple sides. Therefore, the auxiliary reactions can occur on a large fraction of the graphene surface, which is consistent with the significant synergistic capacity enhancement seen in our hybrid samples. The mechanism we propose here may also explain the similar effect previously reported for several other graphene/metal oxides systems (Zhu et al., *ACS Nano* 2011, 5 (4), 3333-3338; Wang et al., *J. Am. Chem. Soc.* 2010, 132 (40), 13978-13980; Wu et al., *ACS Nano* 2010, 4 (6), 3187-3194), although it remains to be confirmed that metal oxide particles in these samples undergo an analogous shape change upon cycling. A significant and verifiable prediction from our hypothesis is that decreasing the particle size of metal oxides will lead to larger graphene-related reversible capacity, as the surface area covered by lithiated particles scales inversely with particle diameter.

By taking advantage of the unique mechanical robustness and high electrical conductance of 3D graphene assembly, we have developed a scalable approach to fabricating additive-free 3D graphene/Fe₂O₃ hybrid electrodes with commercially viable thickness for Li-ion batteries. As anodes graphene/Fe₂O₃ nanoporous films exhibit a high reversible capacity (>850 mAh/g at 100 mA/g), good rate performance and cycling stability. We observe a strong synergistic effect in the hybrids that cannot be offered by the simple conversion reactions of metal oxides or graphene alone. TEM investigations reveal major atomic processes of conversion reactions for Fe₂O₃ and a size-dependent lithiation/delithiation behavior. These mechanistic studies stress the importance of employing nanosized particles in retaining high specific capacity and good rate performance of the hybrid materials. Note that Fe₂O₃ is an insulating material with poor electrical conductivity, which has to rely solely on the 3D graphene networks to deliver electrons and offer mechanical support. Our work thus demonstrates the enabling roles of 3D graphene in providing a conductive network and maintaining structural integrity of the electrodes without the need for carbon additives or polymer binders. Based on the TEM observations, we propose a

graphene surface protection mechanism mediated by metal oxide particle shape change to rationalize the synergistic effect, which may shed light on the pathway towards further optimization of graphene/metal oxide electrodes. Our synthetic method can be extended to other transition metal oxides, and with the availability of relatively cheap graphene materials, is likely to provide a viable route to the fabrication of high-performance electrodes for LIBs

In summary, the working examples help demonstrate a scalable approach to fabricating commercial thickness electrodes, using 3D graphene assembly was developed. The carbon-black- and binder-free graphene/Fe₂O₃ nanoporous materials as anodes exhibited a high reversible capacity (~1166 mAh/g at 100 mA/g current density), good rate performance and cycle stability. A strong synergistic effect in the hybrids was observed that cannot be offered by the simple conversion reactions of metal oxides or graphene alone. The contributions of graphene to the specific capacity and rate performance were drastically improved with the existence of metal oxides. TEM investigations revealed some atomic processes of conversion reactions for Fe₂O₃ and a strong size-dependent lithiation/delithiation behavior. The synthetic method described here is expected to apply to other transition metal oxides as well, and thus provide a viable route to engineering high-performance electrodes for lithium ion batteries.

Conclusion

Despite a number of reports on graphene-based metal oxide anode materials, the prior art approaches are either not easily scalable to large thickness for electrodes or require carbon additives and/or polymeric binders. Reported here is an ultra-thick (~250 μ m), carbon-black-free and binder-free 3-dimensional (3D) graphene/Fe₂O₃ hybrid architecture, where Fe₂O₃ nanoparticles (~12.5 \pm 5.5 nm) are anchored and tented inside graphene networks. The graphene/Fe₂O₃ hybrids are freestanding films and mechanically robust. As an anode material, graphene/Fe₂O₃ offers a large reversible specific capacity of ~1166 mAh/g at the current density of 100 mA/g after 30 cycles, and good rate performance. A strong synergistic behavior between Fe₂O₃ and 3D graphene networks was observed that cannot be offered by the mathematical addition of the conversion reaction of Fe₂O₃ and the lithium intercalations into graphene. Scanning and transmission electron microscopy after various electrochemical cycles revealed the significance of interplay between Fe₂O₃ and graphene, and strong size-dependent electrochemical behavior of metal oxides. The synthetic approach demonstrates a viable scale-up route to constructing graphene/metal oxides as anode materials for Li-ion battery, and further the understanding on the Li storage ability/mechanisms inside the hybrid structures.

The synthesized nanoporous graphene/Fe₂O₃ hybrids as anodes have the following advantageous characteristics: (1) carbon-black- and binder-free. Although graphene has been widely reported as conductive backbone for metal oxides, carbon-black- and binder-free electrodes are rare. (2) Scalability. The nanoporous graphene/Fe₂O₃ hybrids are ready-to-use freestanding nanoporous films, with an impressive thickness of ~250 μ m—which is at least one order of magnitude thicker than any graphene/metal oxides electrodes reported so far. No further processing or mixing is needed. This advantage is a product of the GMA scaffold, which has a large fraction of nanometer-sized pores and an open pore structure, and thus allows the electrolyte in direct contact with most Fe₂O₃ nanoparticles in all portions of the electrode. The small pores physically limit the growth of nanoparticles, significantly shortening the Li ion diffusion

pathway in the anode. In addition, nanopores force multiple sides of nanoparticles in close contact with graphene sheets (see FIG. 1), leading to tented nanoparticle structures that facilitate efficient electron transport to the conductive electrode. As such, the measured specific capacity of the nanoporous graphene/Fe₂O₃ hybrids is essentially thickness independent. This is in contrast to other carbon-black- and binder-free nanoparticle films, which show fast capacity fading as the thickness increases by only a few micrometers (Ha et al., *Nano Lett.* 2012, 12 (10), 5122-5130). (3) High surface area, high electrical conductivity, and mechanical robustness. These properties are attributed to the 3D construction which uses conductive and strong carbon cross-links between graphene sheets and the remarkable properties of individual graphene sheets. This combination of traits is not readily achievable in many other nanoporous materials, which often have low electrical conductivity, low strength, or closed pores, and thus are not suitable for electrode applications.

Example 2

Graphene-TiO₂ Monolith

The TiO₂ sol-gel was prepared via a two-step process involving acid-catalyzed hydrolysis of titanium (IV) ethoxide (1 g) using water (85.7 ml), hydrochloric acid (37%, 71.4 ml), and ethanol (3.57 g), followed by base-initiated gelation using propylene oxide (0.357 g). Composites were synthesized by infiltration of graphene macroassemblies (GMA) by the oxide sol-gel solutions prior to gelation. The graphene monoliths were immersed in the sol-gel solutions and placed under vacuum until no more air escaped from the scaffolds, indicating full penetration of the sol. The concentration of inorganic precursors was kept low to promote the growth of the condensed inorganic phase primarily on the surfaces of the 3D graphene framework, while minimizing gelation in the free pore volume of the aerogel. The infiltrated graphene aerogels were then cured at room temperature for 72 h to produce the wet oxide/GMA gels. The wet oxide/GMA gels were dried using supercritical extraction with liquid CO₂ to yield the final dry oxide/GMA composites. Annealing at 320°C in air for 5 hours was used to convert the TiO₂ to the anatase crystalline phase.

FIGS. 8-11 show x-ray, Raman, and electrochemical characterization.

After annealing, amorphous TiO₂ transit into anatase phase with grain size of ~3 nm.

Li storage capacity decreased from 156 mAh/g to 110 mAh/g in the first delithiation process.

The coulombic efficiencies were similar.

While not limited by theory, the decrease of capacity may be attributed to the oxygen deficiency in the annealed sample.

Example 3

Graphene-SiO₂ Monolith

The graphene macroassembly (GMA) scaffolds were prepared as described in Worsley et al., *Chem. Commun.* 48:8428-8430 (2012). The oxide/GMA composites were prepared through deposition of an oxide coating over the inner surface area of the GMA framework using sol-gel chemistry. The SiO₂ sol-gel was prepared via traditional one-step base-catalyzed alkoxide sol-gel chemistry using tetramethoxysilane (4.1 g), water (1.5 g), ammonium

hydroxide (30%, 200 ml), and methanol (24 g). See Iler, R. K., *The Chemistry of Silica*. 1979, New York: John Wiley & Sons. 896, incorporated herein by reference in its entirety.

Composites were synthesized by infiltration of GMA monoliths by the oxide sol-gel solutions prior to gelation. The GMA's were immersed in the sol-gel solutions and placed under vacuum until no more air escaped from the scaffolds, indicating full penetration of the sol. The concentration of inorganic precursors was kept low to promote the growth of the condensed inorganic phase primarily on the surfaces of the GMA framework, while minimizing gelation in the free pore volume of the aerogel. The infiltrated GMAs were then cured at room temperature for 72 h to produce the wet oxide/GMA gels. The wet oxide/GMA gels were dried using supercritical extraction with liquid CO₂ and annealed to yield the final dry oxide/GMA composites.

Example 4

Graphene-SnO₂ Monolith

The graphene macroassembly (GMA) scaffolds were prepared as described in Worsley et al., *Chem. Commun.* 48:8428-8430 (2012). The oxide/GMA composites were prepared through deposition of an oxide coating over the inner surface area of the GMA framework using sol-gel chemistry. The SnO₂ sol-gel was prepared via an epoxide-initiated gelation method using tin chloride pentahydrate (0.56 g), trimethylene oxide (1.03 g), ethanol (7 g), and water (5 g). See Baumann et al., *Advanced Materials* 17(12): 1546-1548 (2005), incorporated herein by reference in its entirety.

Composites were synthesized by infiltration of GMA monoliths by the oxide sol-gel solutions prior to gelation. The GMA's were immersed in the sol-gel solutions and placed under vacuum until no more air escaped from the scaffolds, indicating full penetration of the sol. The concentration of inorganic precursors was kept low to promote the growth of the condensed inorganic phase primarily on the surfaces of the GMA framework, while minimizing gelation in the free pore volume of the aerogel. The infiltrated GMAs were then cured at room temperature for 72 h to produce the wet oxide/GMA gels. The wet oxide/GMA gels were dried using supercritical extraction with liquid CO₂ and annealed to yield the final dry oxide/GMA composites.

What is claimed is:

1. A composition comprising at least one graphene-supported metal oxide monolith, said monolith comprising (i) a three-dimensional network of graphene sheets crosslinked by covalent carbon bonds, and (ii) at least one metal oxide embedded inside said three-dimensional network, wherein the graphene-supported metal oxide monolith is mesoporous, wherein the graphene-supported metal oxide monolith has a surface area of at least 500 m²/g, wherein the metal oxide accounts for 40-80 wt. % of the graphene-supported metal oxide monolith, and wherein the metal oxide comprises manganese, iron, cobalt, nickel, copper, zinc, zirconium, tin, silicon, aluminum, chromium, vanadium, titanium, or combinations thereof.

2. The composition of claim 1, wherein the graphene sheets are randomly oriented.

3. The composition of claim 1, wherein the covalent carbon bonds for crosslinking the graphene sheets are primarily sp² bonds.

4. The composition of claim 1, wherein the monolith has a thickness of 100 μm or more.

21

5. The composition of claim 1, wherein the metal oxide is in particle form and has an average particle diameter of 50 nm or less.

6. The composition of claim 1, wherein the metal oxide is Fe_2O_3 .

7. The composition of claim 1, wherein the metal oxide is TiO_2 , SiO_2 , or SnO_2 .

8. An electrode comprising the composition of claim 1, wherein the electrode is substantially free of any carbon-black and substantially free of any binder.

9. An electrode comprising the composition of claim 1.

10. A device comprising the electrode of claim 9.

11. The device of claim 10, wherein the monolith is incorporated in an electrode, and wherein the device further comprising at least one counter electrode, at least one electrolyte, at least one separator, and at least one current collector.

12. The device of claim 10, wherein the monolith is incorporated in an electrode, wherein the electrode has a

22

thickness of 100 μm or more, and wherein the electrode is substantially free of any carbon-black and substantially free of any binder.

13. The device of claim 10, wherein the metal oxide is Fe_2O_3 , and wherein the device is a lithium ion battery having a discharge capacity of at least 500 mAh/g at 100 mA/g after 30 cycles.

14. The device of claim 10, wherein the metal oxide is TiO_2 , and wherein the device is a lithium ion battery having a discharge capacity of at least 100 mAh/g at 168 mA/g.

15. The device of claim 10, wherein the device is a battery, a capacitor, or a sensor.

16. The device of claim 10, wherein the graphene sheets are coated by at least one particulate metal oxide.

17. The device of claim 10, wherein the graphene sheets are coated by at least one nanoparticulate metal oxide.
